ABSTRACT

We present a map of the Cosmic Microwave Background (CMB) anisotropies induced by the late Integrated Sachs Wolfe effect. The map is constructed by combining the information of the WMAP 7-yr CMB data and the NRAO VLA Sky Survey (NVSS) through a linear filter. This combination improves the quality of the map that would be obtained using information only from the Large Scale Structure data. In order to apply the filter, a given cosmological model needs to be assumed. In particular, we consider the standard Λ CDM model. As a test of consistency, we show that the reconstructed map is in agreement with the assumed model, which is also favoured against a scenario where no correlation between the CMB and NVSS catalogue is considered.

Key words: cosmology: observations – cosmology: large scale structure – methods: data analysis – methods: statistical

1 INTRODUCTION

Recent observations, as cosmic microwave background (CMB), supernovae type Ia (SNIa) or baryon acoustic oscillations (BAOs) agree in establishing a current accelerated expansion of the Universe (see Weinberg et al. 2012, for a recent review), which, despite some less popular interpretations, is believed to be caused by the presence of some dark energy (see Peebles & Ratra 2003, for a review). The nature of dark energy is one of the most puzzling issues in modern cosmology. The actual characteristics of this fluid is still unclear, although, up to date, a good agreement is found between the observations and the predictions derived from the presence of a cosmological constant with an equation of state $p = -\rho$.

One of the classical probes of dark energy is given by a non-null contribution to the CMB anisotropies from the late integrated Sachs-Wolfe effect (ISW Sachs & Wolfe 1967), under the assumption of a spatially flat universe. The (linear) ISW fluctuations are higher at very large angular scales, but, in any case, much smaller than the primary CMB fluctuations. In a seminal work, Crittenden & Turok (1996) proposed the cross-correlation of the CMB fluctuations and the dark matter distribution (typically traced by galaxy catalogues) as a possible approach to detect the ISW. Soon after the release of the WMAP data, Boughn & Crittenden (2004) reported the first detection of the ISW effect via the CMB

and the galaxy number density field. Posterior works (e.g., Fosalba et al. 2003; Vielva et al. 2006; Pietrobon et al. 2006; Ho et al. 2008; Giannantonio et al. 2008; McEwen et al. 2008; Dupé et al. 2011; Schiavon et al. 2012) have confirmed the detection of the ISW effect by exploring several galaxy catalogues and cross-correlation techniques. Average detection is found at $\approx 3\sigma$.

Besides these works focused on the statistical detection of the ISW, more recently there have been attempts to recover the actual ISW fluctuations on the sky. In principle, an optimal ISW map could be derived from a 3D gravitational potential. This has been explored from very large simulations (e.g., Cai et al. 2010). The complexity to recover optimally the potential from surveys of galaxy with redshift information is challenging (e.g., Kitaura et al. 2009; Jasche et al. 2010), but very promising from the ISW studies point of view (e.g., Frommert et al. 2008).

Other approaches can be followed from surveys where the redshift information is poor, or known only statistically. Barreiro et al. (2008) proposed to use jointly maps of CMB anisotropies and of the galaxy number density field to recover the ISW signal on the sky. Alternative works making use only of galaxy catalogue maps have been proposed afterwards: Granett et al. (2009) on LRGs from SDSS-DR6, or Francis & Peacock (2010) and Dupé et al. (2011) on 2MASS.

This paper presents an application of the approach described in Barreiro et al. (2008) to WMAP (Jarosik et al. 2011) and NVSS (Condon et al. 1998). The outline of the article is as follows. The methodology is reviewed in Section 2. A description of the data used, as well as the fiducial theoretical model is presented in Section 3. In Section 4 we present the results. Finally, conclusions are given in Section 5.

2 METHODOLOGY

In order to reconstruct the ISW map, we have used the linear covariance-based filter presented in Barreiro et al. (2008). We give here the outline of the method.

Since the filter is implemented in harmonic space, for simplicity, we will assume that the considered data sets are full-sky. Let us denote $s_{\ell m}$ and $g_{\ell m}$ to the harmonic coefficients of the ISW map and the large-scale structure (LSS) survey respectively. The covariance matrix $C(\ell)$ of the signals at each multipole ℓ is given by

$$C(\ell) = \begin{pmatrix} C_{\ell}^g & C_{\ell}^{sg} \\ C_{\ell}^{sg} & C_{\ell}^s \end{pmatrix} \quad (1)$$

where C_{ℓ}^g and C_{ℓ}^s correspond to the auto spectra of the galaxies and ISW maps, respectively, while C_{ℓ}^{sg} is the cross power between both signals. To construct the filter, we will make use of the Cholesky decomposition of the covariance matrix, which satisfies $C(\ell) = L(\ell)L^T(\ell)$, where $L(\ell)$ is a lower triangular matrix. It can be trivially shown that the elements of the Cholesky matrix relate to the elements of $C(\ell)$ as $L_{11} = \sqrt{C_{\ell}^g}$, $L_{12} = C_{\ell}^{sg}/\sqrt{C_{\ell}^g}$ and $L_{22} = \sqrt{|C(\ell)|/C_{\ell}^g}$, where $|C(\ell)|$ is the determinant of the covariance matrix at each ℓ mode.

The estimated ISW map $\hat{s}_{\ell m}$ at each harmonic mode is given by (see Barreiro et al. 2008 for details)

$$\hat{s}_{\ell m} = \frac{L_{12}(\ell)}{L_{11}(\ell)} g_{\ell m} + \frac{L_{22}^2(\ell)}{L_{22}^2(\ell) + C_{\ell}^n} \left(d_{\ell m} - \frac{L_{12}(\ell)}{L_{11}(\ell)} g_{\ell m} \right) \quad (2)$$

where $d_{\ell m}$ are the harmonic coefficients of the CMB map and C_{ℓ}^n is the power spectrum of the CMB signal without including the ISW. Therefore, to reconstruct the ISW map, we need to assume an underlying cosmological model that determines the auto and cross power spectra present in the previous equation.

It is interesting to note that the final reconstructed map has two contributions: the first term in the previous equation is given by a filtered version of the galaxies map while the second expression is a Wiener filter (WF, Wiener 1949) of a modified CMB data map. This modified data is simply constructed as the original CMB map minus the filtered survey. In the case that there is not correlation between the CMB and the LSS survey, the filter simply defaults to the WF of the CMB map: since there is not correlation between both signals, the galaxies map does not contribute to the final ISW reconstruction. If the information provided by the CMB map were not considered, the estimated ISW would be given just by the filtered galaxies map.

It can be easily shown that the expected value of the power spectrum of the estimated ISW is given by

$$\langle C_{\ell}^{\hat{s}} \rangle = \frac{(C_{\ell}^{sg})^2 (|C(\ell)| + C_{\ell}^g C_{\ell}^n) + |C(\ell)|^2}{C_{\ell}^g (|C(\ell)| + C_{\ell}^g C_{\ell}^n)} \quad (3)$$

It is well known that the power spectrum of the WF reconstruction is biased towards values lower than the true signal, with the bias depending on the signal-to-noise ratio of the data. Since our signal is partially reconstructed using this filter, it will also be biased. The larger the cross-correlation between CMB and the considered galaxies catalogue, the smaller the bias, since the WF part will contribute relatively less than the filtered survey term (see Barreiro et al. 2008 for details).

It is also straightforward to show that the expected cross-correlation between the recovered signal and the galaxies catalogue is equal to that of the assumed model. However, this is only correct if the assumed cross and auto power spectra reflects the underlying statistical properties between the ISW and the LSS survey. In practice, the difference between the expected values of the previous quantities for two (reasonably) different models will in general be small and, given the weakness of the signal and the statistical uncertainties, it may be difficult to discriminate between them. In any case, as we will see in Section 4, the comparison between the expected and estimated values of the cross-correlation is an interesting consistency check.

The previous description assumes that full-sky data are available. However, in practice, a mask will be needed to exclude those regions, in both CMB and galaxies survey maps, that have not been observed or are too contaminated to be included in the analysis. In Barreiro et al. (2008) was shown that the method was robust against the presence of a mask and that the quality of the reconstruction was not significantly affected. Therefore, to deal with this problem, we will simply substitute in the previous equations the harmonic coefficients and power spectra by those obtained after masking the data with the considering mask. In particular, the *masked* version of the fiducial model for the power spectra will be obtained *ala* MASTER (Hivon et al. 2002). In addition, we will make use of an apodised version of the considered mask in order to reduce the correlations between harmonic modes that are introduced on an incomplete sky.

3 DATA DESCRIPTION

In order to reconstruct the ISW map using the previous methodology, we need both a CMB map and a LSS catalogue, as well as a cosmological fiducial model. For the latter, we have assumed a Λ CMD model that best fits 7-yr WMAP data, BAO and H_0 measurements (Komatsu et al. 2011).

For the CMB, we have made use of the 7-yr WMAP data (Jarosik et al. 2011) publicly available at the Legacy Archive for Microwave Background Data Analysis¹. In particular, we have constructed a CMB map as a noise-weighted combination of the foreground reduced V- and W-band maps. The map has then been downgraded to a HEALPix resolution of $N_{\text{side}} = 32$. To reduce the galactic foreground contamination, the KQ85 mask provided by the WMAP team has been used. However, since we have to downgrade the mask to a lower resolution, we have not included in the mask the holes due to point sources since their contribution is expected to be negligible at the considered scales. The

Figure 1. Top: WMAP 7-yr data (in Kelvin thermodynamic temperature). Middle: NVSS galaxy density number field. Bottom: apodised mask used for the analysis.

WMAP data, with the considered mask applied, is given in the top panel of Fig. 1.

Regarding the LSS catalogue, we have used the NRAO VLA Sky Survey (NVSS, Condon et al. 1998). NVSS covers the north hemisphere of the sky and part of the south until $\delta = -40^\circ$. The NVSS catalogue has nearly 2×10^6 discrete sources with fluxes above 2.5 mJy. The catalogue was made using two different configurations (D and DnC) of the Very Large Array (VLA). This introduced a declination dependence in the number of sources, specially for the faintest ones. Sources above 5.0 mJy have been selected to build a catalogue not affected by this declination effect. The NVSS mask is defined by the unobserved sky, plus the sources within 7 degrees from the galactic plane, as well as some regions associated to very near objects. The complete mask associated to NVSS leaves 73% of the sky. The map is shown in the middle panel of Fig. 1.

The ISW-NVSS angular cross-power spectrum is calculated using the galaxy redshift distribution proposed by de Zotti et al. (2010): a polynomial fit to the CENSORS data (Brookes et al. 2008). For the galaxy bias is assumed a redshift dependence as the one proposed by Xia et al.

(2011), where the bias is just defined by the minimum halo mass associated to NVSS radio-galaxies. The value of this mass is determined by fitting the NVSS angular power spectrum (see Marcos-Caballero et al. 2012, , in preparation, for details).

As it is well known (e.g. Hernández-Monteagudo 2010), there is a clear discrepancy between the measured NVSS auto power spectrum and the theoretical model as described above. In particular, an excess of power at low multipoles is observed. This deviation does not seem to be related to the declination effect previously mentioned, since it is observed even for the angular power spectrum estimated from very bright sources. A possible explanation in terms of a non-linear evolution of the galaxy bias (caused by a primordial non-Gaussianity of the primordial perturbations) has been considered by Xia et al. (2011), although it would imply a value of the non-linear coupling parameter f_{NL} larger than the one obtained from other observables (as the CMB bispectrum estimated from WMAP; see, for instance, Curto et al. 2011). Currently, the nature of this discrepancy is not clear. Since the filter described in the previous section (see equation 2) is very sensitive to the value of the auto-power spectrum of the galaxy survey, we have used as fiducial C_ℓ^g a smooth fit to the observed NVSS spectrum.

Finally, we have combined the WMAP and NVSS masks, leaving a useful area of 66%. The mask is then apodised using a cosine function, in order to reduce the correlations among the harmonic modes of the incomplete sky. This apodised mask (see bottom panel of Fig. 1) is applied to the CMB and NVSS data prior to the reconstruction of the ISW map. In addition, the monopole and dipole outside the combined mask are subtracted prior to the construction of the ISW map.

4 ISW RECONSTRUCTION

Following the described methodology, we have produced an ISW map from the WMAP and NVSS data. The map is given in Fig. 2 and has been constructed at a HEALPix resolution of $N_{side} = 32$ and up to a maximum multipole $l = 95$.

As a consistency test, we have obtained the cross correlation between the reconstructed ISW map and the NVSS data and compared it with the fiducial model. The former has been simply obtained as the pseudo cross spectrum from the masked maps and then corrected *ala MASTER*. In addition, we have also repeated the same procedure on two sets of 10000 simulations. For the first set, we have constructed correlated CMB and NVSS-like simulations (generated as explained in Barreiro et al. 2008), assuming the same power spectra as for reconstructing the ISW map. For the second set, the autospectra are the same but zero correlation is assumed between the CMB and NVSS simulations. In both cases, we have included the corresponding Poissonian noise in the simulations of the galaxies catalogue. The results for this test are given in Fig. 3.

As expected, the average value (red triangles) for the correlated simulations agrees well with the considered model (black line). More interestingly, the data (blue asterisks) are also compatible with these simulations, which provides a good consistency check for our procedure and indicates that

Figure 2. Reconstructed ISW map. Units are Kelvin (thermodynamic temperature).

the assumed cross and auto spectra are reasonably close to the true statistical properties of the sky.

Conversely, the average obtained from the uncorrelated simulations (green squares) are biased with respect to the assumed cross spectrum. This is expected, since the assumed model is not the same as the underlying true power spectrum. Unfortunately, since the signal is very weak, the difference between both models is also small and it is difficult to distinguish between both hypotheses in the basis of this test.

To try to quantify which hypothesis is favoured by the data, we have calculated the goodness-of-fit difference:

$$\Delta\chi^2 = \chi_c^2 - \chi_u^2,$$

where

$$\chi_i^2 = \mathbf{c}_{\text{sg}} \mathbf{M}_i^{-1} \mathbf{c}_{\text{sg}}^T, \quad (4)$$

$i \equiv \{c, u\}$, and \mathbf{c}_{sg} correspond to the vector constructed with the values of the binned cross power spectrum. \mathbf{M}_c is the covariance matrix of the cross-spectrum obtained from 10000 correlated simulations and \mathbf{M}_u the same matrix for the uncorrelated simulations set. We have calculated the distribution of this quantity from independent sets of 10000 correlated and uncorrelated simulations and compare it to the value found for the data. In particular, we find $\Delta\chi^2(\text{data}) = -2.4$. For the correlated CMB and galaxies survey simulations, we find that 28.9 per cent of the simulations have a value larger than the one obtained for the data. This percentage is reduced to 6.7 per cent, when we compare the data with the distribution obtained for uncorrelated simulations. Therefore, although the data are in fact compatible with the two cases considered, it favours the hypothesis of having an underlying correlation. This further confirms the consistency of our results.

Although, given the weakness of the considered cross-correlation, the power of these tests is somewhat limited, the fact that the data shows consistency with the assumed model should not be taken for granted, since other assumptions may also affect the results. For instance, if we use the theoretical model for the auto spectrum of the NVSS map, instead of a smooth fit to the measured data (as explained in section 3), we find a clear departure of the cross correlation between the reconstructed ISW map and the NVSS data with respect to the expected value.

Using simulations, we have also studied which is the improvement from combining both the CMB and NVSS data, with respect to use only the galaxies catalogue (as for instance in Dupé et al. 2011 whose proposed reconstruction corresponds to the term given by the filtered survey of equation 2). In particular, we find an improvement of 15 per cent in the error of the ISW reconstruction when the CMB data is included. In any case, the relative contribution to the reconstruction of the CMB and LSS data depend significantly on the cross correlation between them, so it will differ for other galaxies surveys.

In a related matter, we can also calculate the expected relative contribution of the auto and cross power of the CMB and the galaxy number density maps to the angular power spectrum of the reconstructed ISW map (using equation 2). This is shown in Fig. 4 for the fiducial model as well as the actual contribution of each angular power spectrum for the considered data. As can be seen, the contribution from the power spectrum of the CMB C_ℓ^{tt} is dominant at low multipoles (up to $\ell \approx 10$), while C_ℓ^{gg} gives the main weight at higher multipoles. The contribution from the cross power between the CMB and NVSS is subdominant at all multipoles. The results obtained from the data agrees quite well with the expected value. However, it is interesting to point

Figure 3. The binned cross-correlation between the reconstructed ISW map and the NVSS data is given (blue asterisks). For comparison, the fiducial model (black line) and the average and dispersion from two sets of 10000 simulations are also shown. The red triangles and their error bars correspond to CMB and NVSS-like simulations which are correlated, while for the second set of simulations (green squares are error bars), no correlation is introduced. The width of the bins is $\Delta_\ell = 9$, except for the last bin that is $\Delta_\ell = 13$. For a better visualization, the results for the simulations have been shifted with respect to the central value of the bin.

Figure 4. The expected relative contribution of the CMB and NVSS auto and cross spectra to the power spectrum of the ISW reconstruction is shown (solid lines) as well as the same quantities for the data. The results for the data have been binned to allow for a clearer comparison. The error bars correspond to the dispersion of the values within the considered bin.

out that the relative importance of C_ℓ^{tt} with respect to C_ℓ^{gg} for the data is lower than the expectation value. This can be easily explained by the fact that the amplitude of the low multipoles of the WMAP data is lower than that of the fiducial model.

5 CONCLUSIONS

We have presented a reconstructed map of the ISW effect, obtained by combining through a linear filter CMB and LSS

data. In particular, we have used the 7-yr WMAP data and the NVSS galaxies catalogue. The joint combination of both data sets improve in a 15 per cent the error of the ISW reconstruction in comparison to the case when only the NVSS data are used. We have performed a consistency test, showing a good agreement between the cross correlation inferred from the reconstructed ISW map and the assumed fiducial model. In particular, the data favours a Λ CDM model with respect to a scenario with null correlation between the CMB and the NVSS data. The relative contribution to the angular power spectrum of the ISW reconstructed map is dominated by the CMB fluctuations up to $\ell \approx 10$ and by the density number galaxies field at larger multipoles.

The presented methodology works in harmonic space, which implies the use of surveys with large sky coverage, in order to avoid the problematics introduced by large masks. However, this technique can be easily extended to work directly in the pixel space, which would make straightforward to deal with a mask and, in particular, LSS surveys with smaller sky coverage could also be used to reconstruct the ISW signal (Bonavera et al. 2012, in preparation). In addition, several catalogues can be combined at the same time, provided the covariance matrix between the surveys and the CMB data are known.

Finally, let us remark that the application of the approach described in this paper to future surveys (as EUCLID Refregier et al. 2010 or J-PAS Benítez et al. 2009, with very large sky coverage and very accurate redshift estimation) could provide maps of the ISW anisotropies caused by the large-scale structure at different redshift shells. This will provide a tomographic view of the ISW fluctuations.

ACKNOWLEDGEMENTS

The authors thank Andrés Curto, Raúl Fernández-Cobos and Francesco Paci for useful discussions.
